

Analysis and Design of Algorithms

Unit I

What Is an Algorithm?

- An *algorithm* is a sequence of unambiguous instructions for solving a problem, i.e., for obtaining a required output for any legitimate input in a finite amount of time.
- As examples illustrating the notion of the algorithm, we consider in this section three methods for solving the same problem: computing the greatest common divisor of two integers.

URE 1.1 The notion of the algorithm.

- **Steps for writing an algorithm:**

1. An algorithm is a procedure. It has two parts; the **first part is head** and the **second part is body**.

2. The Head section consists of keyword Algorithm and Name of the algorithm with parameter list. E.g. Algorithm name1(p1, p2,...,p3) The head section also has the following:

 //Problem Description:

 //Input:

 //Output:

3. In the body of an algorithm various programming **constructs like if, for, while** and some statements like assignments are used.

4. The compound statements may be **enclosed with { and } brackets. if, for, while can be closed by endif, endfor, endwhile** respectively. Proper indention is must for block.

5. Comments are written using // at the beginning.

6. The identifier **should begin by a letter and not by digit**. It contains alpha numeric letters after first letter. No need to mention data types.
7. The left arrow “ \leftarrow ” used as assignment operator. E.g. $v \leftarrow 10$
8. Boolean operators (TRUE, FALSE), Logical operators (AND, OR, NOT) and Relational operators ($<$, \leq , $>$, \geq , $=$, \neq , $<>$) are also used.
9. Input and Output can be done using read and write.
10. Array[], if then else condition, branch and loop can be also used in algorithm.

- These examples will help us to illustrate several important points:
 - The **nonambiguity requirement** for each step of an algorithm cannot be compromised.
 - The **range of inputs** for which an algorithm works has to be **specified carefully**.
 - The **same algorithm** can be represented in **several different ways**.
 - There may exist **several algorithms for solving the same problem**.
 - Algorithms for the same problem can be based on very different ideas and can **solve the problem with dramatically different speeds**.

Here is a more structured description of this algorithm.

Euclid's algorithm for computing $\text{gcd}(m, n)$

Step 1 If $n = 0$, return the value of m as the answer and stop; otherwise, proceed to Step 2.

Step 2 Divide m by n and assign the value of the remainder to r .

Step 3 Assign the value of n to m and the value of r to n . Go to Step 1.

Alternatively, we can express the same algorithm in pseudocode:

ALGORITHM *Euclid*(m, n)

//Computes $\text{gcd}(m, n)$ by Euclid's algorithm

//Input: Two nonnegative, not-both-zero integers m and n

//Output: Greatest common divisor of m and n

while $n \neq 0$ **do**

$r \leftarrow m \bmod n$

$m \leftarrow n$

$n \leftarrow r$

return m

- The first is simply based on the definition of the greatest common divisor of m and n as the largest integer that divides both numbers evenly. Obviously, such a common divisor cannot be greater than the smaller of these numbers, which we will denote by $t = \min\{m, n\}$. So we can start by checking whether t divides both m and n : if it does, t is the answer; if it does not, we simply decrease t by 1 and try again. (How do we know that the process will eventually stop?)
- For example, for numbers 60 and 24, the algorithm will try first 24, then 23, and so on, until it reaches 12, where it stops.

Consecutive integer checking algorithm for computing $\gcd(m, n)$

Step 1 Assign the value of $\min\{m, n\}$ to t .

Step 2 Divide m by t . If the remainder of this division is 0, go to Step 3; otherwise, go to Step 4.

Step 3 Divide n by t . If the remainder of this division is 0, return the value of t as the answer and stop; otherwise, proceed to Step 4.

Step 4 Decrease the value of t by 1. Go to Step 2.

- Note that unlike Euclid's algorithm, this algorithm, in the form presented, does not work correctly when one of its input numbers is zero.
- This example illustrates why it is so important to specify the set of an algorithm's inputs explicitly and carefully.

- The third procedure for finding the greatest common divisor should be familiar to you from middle school.

Middle-school procedure for computing $\gcd(m, n)$

Step 1 Find the prime factors of m .

Step 2 Find the prime factors of n .

Step 3 Identify all the common factors in the two prime expansions found in Step 1 and Step 2. (If p is a common factor occurring p_m and p_n times in m and n , respectively, it should be repeated $\min\{p_m, p_n\}$ times.)

Step 4 Compute the product of all the common factors and return it as the greatest common divisor of the numbers given.

Thus, for the numbers 60 and 24, we get

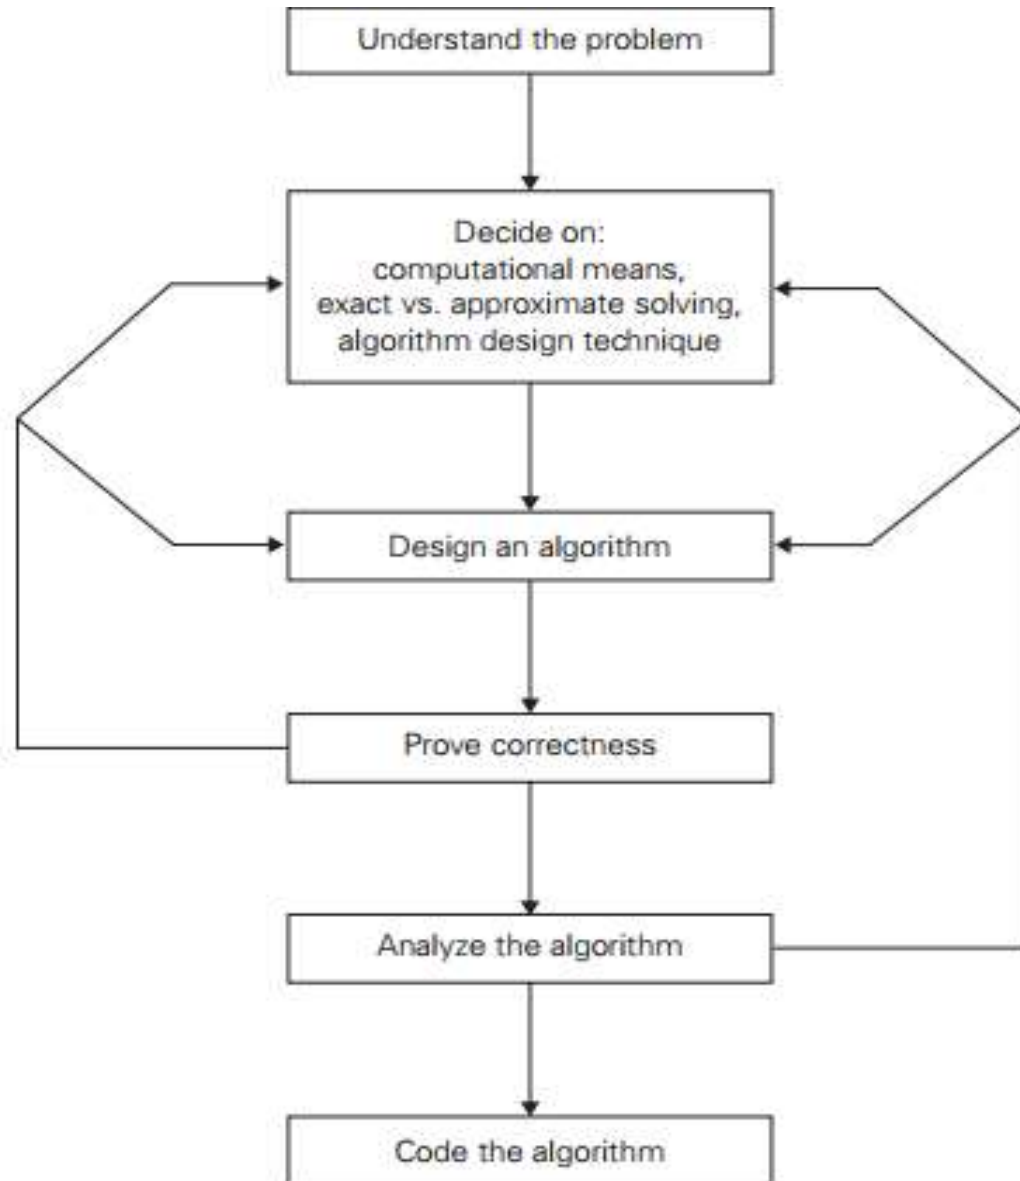

$$60 = 2 \cdot 2 \cdot 3 \cdot 5$$

$$24 = 2 \cdot 2 \cdot 2 \cdot 3$$

$$\gcd(60, 24) = 2 \cdot 2 \cdot 3 = 12.$$

- Nostalgia for the days when we learned this method should not prevent us from noting that the last procedure is much more complex and slower than Euclid's algorithm.
- In addition to inferior efficiency, the middle school procedure does not qualify, in the form presented, as a legitimate algorithm. Why? Because the prime factorization steps are not defined unambiguously: they require a list of prime numbers.

Fundamentals of Algorithmic Problem Solving

URE 1.2 Algorithm design and analysis process.

- **Understanding the Problem :**

This is the first step in designing of algorithm.

- **Read the problem's description** carefully to **understand the problem** statement completely.
- Ask questions for clarifying the doubts about the problem.
- Identify the problem types and use existing algorithm to find solution.
- Input (instance) to the problem and range of the input get fixed.

- (ii) **Decision making**
- The Decision making is done on the following:
- (a) **Ascertaining the Capabilities of the Computational Device**
 - In Random-Access Machine (RAM), instructions are executed one after another (The central assumption is that one operation at a time). Accordingly, algorithms designed to be executed on such machines are called **sequential algorithms**.
 - In some newer computers, operations are executed concurrently, i.e., in parallel. Algorithms that take advantage of this capability are called **parallel algorithms**.
 - Choice of computational devices like Processor and memory is mainly based on space and time efficiency

(b) Choosing between Exact and Approximate Problem Solving

- The next principle decision is to choose between solving the problem exactly or solving it approximately.
- An algorithm used to solve the problem exactly and produce correct result is called an exact algorithm.
- If the problem is so complex and not able to get exact solution, then we have to choose an algorithm called an approximation algorithm. i.e., produces an approximate answer. E.g., extracting square roots, solving nonlinear equations, and evaluating definite integrals.

(c) **Algorithm Design Techniques**

- An algorithm design technique (or “strategy” or “paradigm”) is a general approach to solving problems algorithmically that is applicable to a variety of problems from different areas of computing.
- **Algorithms+ Data Structures = Programs**
- Though **Algorithms and Data Structures are independent**, but they are combined together to develop program. Hence the choice of proper data structure is required before designing the algorithm.
- Implementation of algorithm is possible only with the help of Algorithms and Data Structures
- Algorithmic strategy / technique / paradigm are a general approach by which many problems can be solved algorithmically. E.g., Brute Force, Divide and Conquer, Dynamic Programming, Greedy Technique and so on.

(iii) Methods of Specifying an Algorithm

There are three ways to specify an algorithm. They are:

- a. **Natural language**
- b. **Pseudocode**
- c. **Flowchart**

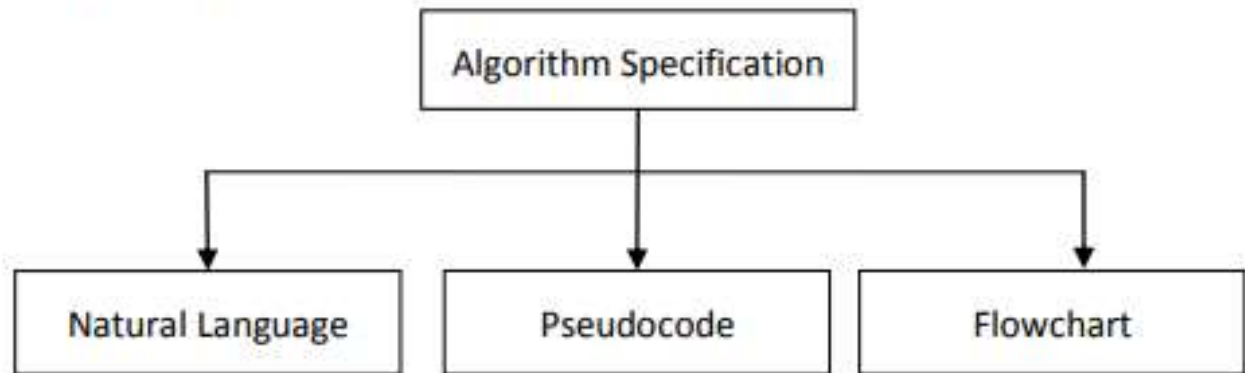

FIGURE 1.3 Algorithm Specifications

- **a. Natural Language**
- It is very simple and easy to specify an algorithm using natural language. But many times specification of algorithm by using natural language is not clear and thereby we get brief specification. Example: An algorithm to perform addition of two numbers.
 - Step 1: Read the first number, say a.
 - Step 2: Read the second number, say b.
 - Step 3: Add the above two numbers and store the result in c.
 - Step 4: Display the result from c.
- Such a specification creates difficulty while actually implementing it.
- Hence many programmers prefer to have specification of algorithm by means of Pseudocode.

b. Pseudocode

- Pseudocode is a mixture of a natural language and programming language constructs. Pseudocode is usually more precise than natural language.
- For Assignment operation left arrow " \leftarrow ", for comments two slashes "//", **if** condition, **for**, **while** loops are used.

ALGORITHM *Sum(a,b)*

//Problem Description: This algorithm performs addition of two numbers

//Input: Two integers a and b

//Output: Addition of two integers

$c \leftarrow a + b$

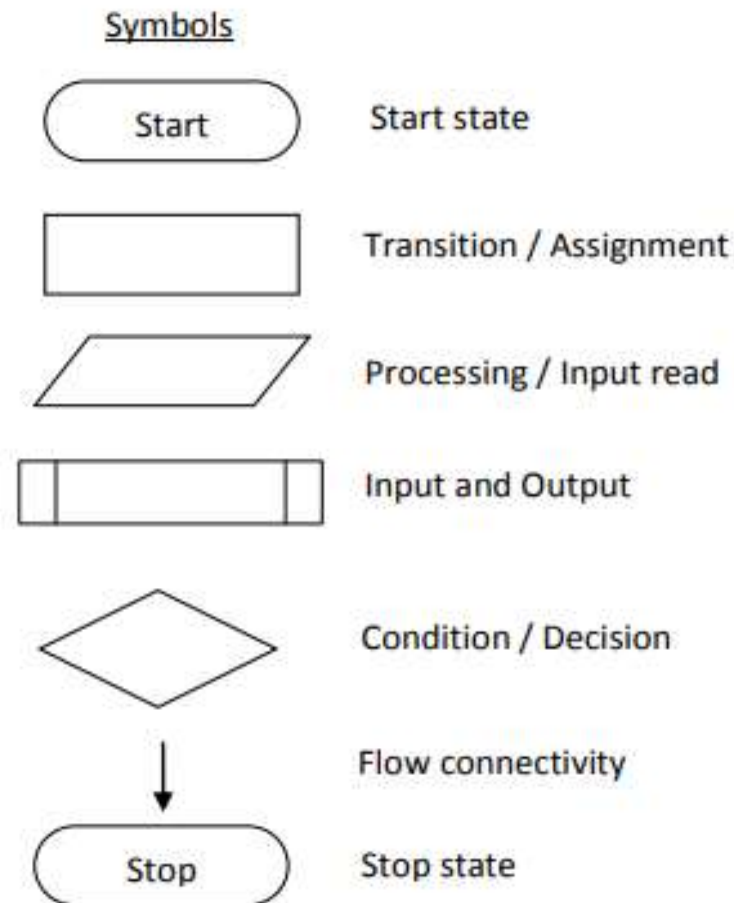

return c

This specification is more useful for implementation of any language.

c. Flowchart

In the earlier days of computing, the dominant method for specifying algorithms was a *flowchart*, this representation technique has proved to be inconvenient.

Flowchart is a graphical representation of an algorithm. It is a a method of expressing an algorithm by a collection of connected geometric shapes containing descriptions of the algorithm's steps.

Example: Addition of a and b

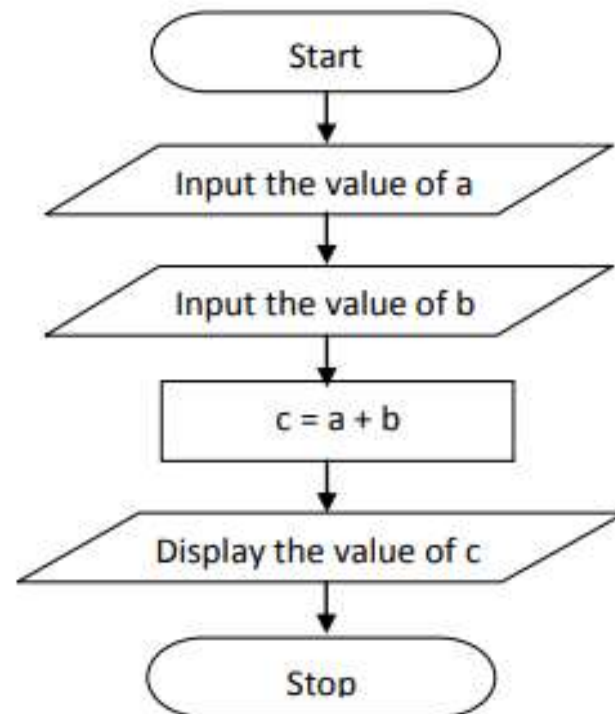

FIGURE 1.4 Flowchart symbols and Example for two integer addition.

(iv) Proving an Algorithm's Correctness

- Once an algorithm has been specified then its correctness must be proved.
- An algorithm must yields a required result for **every legitimate(reasonable) input in a finite amount of time.**
- For example, the correctness of Euclid's algorithm for computing the greatest common divisor steps from the correctness of the equality $\text{gcd}(m, n) = \text{gcd}(n, m \bmod n)$.
- A common technique for proving correctness is to use mathematical induction because an algorithm's iterations provide a natural sequence of steps needed for such proofs.
- The notion of correctness for approximation algorithms is less straightforward than it is for exact algorithms. The error produced by the algorithm should not exceed a predefined limit.

(v) Analyzing an Algorithm

- For an algorithm the most important is efficiency. In fact, there are two kinds of algorithm efficiency.
- They are:
 - Time efficiency, indicating how fast the algorithm runs, and
 - Space efficiency, indicating how much extra memory it uses.
- The efficiency of an algorithm is determined by measuring both time efficiency and space efficiency. ☐
So factors to analyze an algorithm are:
 - Time efficiency of an algorithm
 - Space efficiency of an algorithm
 - Simplicity of an algorithm
 - Generality of an algorithm

- **(vi) Coding an Algorithm**
- The coding / implementation of an algorithm is done by a suitable programming language like C, C++, JAVA.
- The transition from an algorithm to a program can be done either incorrectly or very inefficiently. Implementing an algorithm correctly is necessary. The Algorithm power should not be reduced by inefficient implementation.
- Standard tricks like computing a loop's invariant (an expression that does not change its value) outside the loop, collecting common subexpressions, replacing expensive operations by cheap ones, selection of programming language and so on should be known to the programmer.
- Typically, such improvements can speed up a program only by a constant factor, whereas a better algorithm can make a difference in running time by orders of magnitude. But once an algorithm is selected, a 10–50% speedup may be worth an effort.
- It is very essential to write an optimized code (efficient code) to reduce the burden of compiler.

- **IMPORTANT PROBLEM TYPES**
- The most important problem types are:
 - (i). Sorting
 - (ii). Searching
 - (iii). String processing
 - (iv). Graph problems
 - (v). Combinatorial problems
 - (vi). Geometric problems
 - (vii). Numerical problems

(i) Sorting

- The sorting problem is to rearrange the items of a given list in nondecreasing (ascending) order.
- Sorting can be done on numbers, characters, strings or records.
- To sort student records in alphabetical order of names or by student number or by student grade-point average. Such a specially chosen piece of information is called a key.
- An algorithm is said to be in-place if it does not require extra memory, E.g., Quick sort.
- A sorting algorithm is called stable if it preserves the relative order of any two equal elements in its input.

(ii) Searching

- The searching problem deals with finding a given value, called a search key, in a given set.
 - E.g., Ordinary Linear search and fast binary search.

(iii) String processing

- A string is a sequence of characters from an alphabet.
- Strings comprise letters, numbers, and special characters; bit strings, which comprise zeros and ones; and gene sequences, which can be modeled by strings of characters from the four character alphabet {A, C, G, T}. It is very useful in bioinformatics.
- Searching for a given word in a text is called string matching

(iv) Graph problems

- A graph is a collection of points called vertices, some of which are connected by line segments called edges.
- Some of the graph problems are graph traversal, shortest path algorithm, topological sort, traveling salesman problem and the graph-coloring problem and so on.

(v) Combinatorial problems

- A combinatorial problem consists in, **given a finite collection of objects and a set of constraints, finding an object of the collection that satisfies all constraints** (and possibly that optimizes some objective function). Combinatorial problems are ubiquitous and have an enormous practical importance.
- A desired combinatorial object may also be required to have some additional property such as a maximum value or a minimum cost.
- In practical, the combinatorial problems are the most difficult problems in computing.
- The traveling salesman problem and the graph coloring problem are examples of combinatorial problems.

(vi) Geometric problems

- Geometric algorithms deal with geometric objects such as points, lines, and polygons.
- Geometric algorithms are used in computer graphics, robotics, and tomography.
- The closest-pair problem and the convex-hull problem are comes under this category.

(vii) Numerical problems

- Numerical problems are problems that involve mathematical equations, systems of equations, computing definite integrals, evaluating functions, and so on.
- The majority of such mathematical problems can be solved only approximately.

FUNDAMENTALS OF THE ANALYSIS OF ALGORITHM EFFICIENCY

- The efficiency of an algorithm can be in terms of time and space. The algorithm efficiency can be analyzed by the following ways.
 - Analysis Framework.
 - Asymptotic Notations and its properties.
 - Mathematical analysis for Recursive algorithms.
 - Mathematical analysis for Non-recursive algorithms.

Analysis Framework

There are two kinds of efficiencies to analyze the efficiency of any algorithm.

They are:

- Time efficiency, indicating how fast the algorithm runs, and
- Space efficiency, indicating how much extra memory it uses.

The algorithm analysis framework consists of the following:

- Measuring an Input's Size
- Units for Measuring Running Time
- Orders of Growth
- Worst-Case, Best-Case, and Average-Case Efficiencies

- **(i) Measuring an Input's Size**

- An algorithm's efficiency is defined as a function of some parameter n indicating the algorithm's input size. In most cases, selecting such a parameter is quite straightforward. For example, it will be the size of the list for problems of sorting, searching.
- For the problem of evaluating a polynomial $p(x) = a_n x^n + \dots + a_0$ of degree n , the size of the parameter will be the polynomial's degree or the number of its coefficients, which is larger by 1 than its degree.
- In computing the product of two $n \times n$ matrices, the choice of a parameter indicating an input size does matter.
- Consider a spell-checking algorithm. If the algorithm examines individual characters of its input, then the size is measured by the number of characters.
- In measuring input size for algorithms solving problems such as checking primality of a positive integer n . the input is just one number.
- The input size by the number b of bits in the n 's binary representation is $b = (\log_2 n) + 1$.

- **(ii) Units for Measuring Running Time**

Some standard unit of time measurement such as a second, or millisecond, and so on can be used to measure the running time of a program after implementing the algorithm.

Drawbacks

- Dependence on the speed of a particular computer.
- Dependence on the quality of a program implementing the algorithm.
- The compiler used in generating the machine code.
- The difficulty of clocking the actual running time of the program.

So, we need metric to measure an algorithm's efficiency that does not depend on these extraneous factors. One possible approach is to count the number of times each of the algorithm's operations is executed. This approach is excessively difficult.

The most important operation (+, -, *, /) of the algorithm, called the basic operation. Computing the number of times the basic operation is executed is easy. The total running time is determined by basic operations count.

(iii) Orders of Growth

- A difference in running times on small inputs is not what really distinguishes efficient algorithms from inefficient ones.
- For example, the greatest common divisor of two small numbers, it is not immediately clear how much more efficient Euclid's algorithm is compared to the other algorithms, the difference in algorithm efficiencies becomes clear for larger numbers only.
- For large values of n , it is the function's order of growth that counts just like the Table 1.1, which contains values of a few functions particularly important for analysis of algorithms.

TABLE 1.1 Values (approximate) of several functions important for analysis of algorithms

n	\sqrt{n}	$\log_2 n$	n	$n \log_2 n$	n^2	n^3	2^n	$n!$
1	1	0	1	0	1	1	2	1
2	1.4	1	2	2	4	4	4	2
4	2	2	4	8	16	64	16	24
8	2.8	3	8	$2.4 \cdot 10^1$	64	$5.1 \cdot 10^2$	$2.6 \cdot 10^2$	$4.0 \cdot 10^4$
10	3.2	3.3	10	$3.3 \cdot 10^1$	10^2	10^3	10^3	$3.6 \cdot 10^6$
16	4	4	16	$6.4 \cdot 10^1$	$2.6 \cdot 10^2$	$4.1 \cdot 10^3$	$6.5 \cdot 10^4$	$2.1 \cdot 10^{13}$
10^2	10	6.6	10^2	$6.6 \cdot 10^2$	10^4	10^6	$1.3 \cdot 10^{30}$	$9.3 \cdot 10^{157}$
10^3	31	10	10^3	$1.0 \cdot 10^4$	10^6	10^9	Very big computation	
10^4	10^2	13	10^4	$1.3 \cdot 10^5$	10^8	10^{12}		
10^5	$3.2 \cdot 10^2$	17	10^5	$1.7 \cdot 10^6$	10^{10}	10^{15}		
10^6	10^3	20	10^6	$2.0 \cdot 10^7$	10^{12}	10^{18}		

- **(iv) Worst-Case, Best-Case, and Average-Case Efficiencies**

Consider Sequential Search algorithm some search key K

ALGORITHM *SequentialSearch*($A[0..n - 1]$, K)

//Searches for a given value in a given array by sequential search

//Input: An array $A[0..n - 1]$ and a search key K

//Output: The index of the first element in A that matches K or -1 if there are no

// matching elements

$i \leftarrow 0$

while $i < n$ **and** $A[i] \neq K$ **do**

$i \leftarrow i + 1$

if $i < n$ **return** i

else return -1

Clearly, the running time of this algorithm can be quite different for the same list size n .

In the worst case, there is no matching of elements or the first matching element can found at last on the list. In the best case, there is matching of elements at first on the list.

- **Worst-case efficiency**

- The worst-case efficiency of an algorithm is its efficiency for the worst case input of size n .
- The algorithm runs the longest among all possible inputs of that size.
- For the input of size n , the running time is $C_{worst}(n) = n$.

- **Best case efficiency**

- The best-case efficiency of an algorithm is its efficiency for the best case input of size n .
- The algorithm runs the fastest among all possible inputs of that size n .
- In sequential search, If we search a first element in list of size n . (i.e. first element equal to a search key), then the running time is $C_{best}(n) = 1$

Average case efficiency

- The Average case efficiency lies between best case and worst case.
- To analyze the algorithm's average case efficiency, we must make some assumptions about possible inputs of size n .
- The standard assumptions are that
 - The probability of a successful search is equal to p ($0 \leq p \leq 1$) and
 - The probability of the first match occurring in the i th position of the list is the same for every i .

$$\begin{aligned}C_{avg}(n) &= \left[1 \cdot \frac{p}{n} + 2 \cdot \frac{p}{n} + \dots + i \cdot \frac{p}{n} + \dots + n \cdot \frac{p}{n}\right] + n \cdot (1 - p) \\&= \frac{p}{n} [1 + 2 + \dots + i + \dots + n] + n(1 - p) \\&= \frac{p}{n} \frac{n(n+1)}{2} + n(1 - p) = \frac{p(n+1)}{2} + n(1 - p).\end{aligned}$$

Yet another type of efficiency is called ***amortized efficiency***. It applies not to a single run of an algorithm but rather to a sequence of operations performed on the same data structure.

ASYMPTOTIC NOTATIONS AND ITS PROPERTIES

Asymptotic notation is a notation, which is used to take meaningful statement about the efficiency of a program.

The efficiency analysis framework concentrates on the order of growth of an algorithm's basic operation count as the principal indicator of the algorithm's efficiency.

To compare and rank such orders of growth, computer scientists use three notations, they are:

- O - Big oh notation
- Ω - Big omega notation
- Θ - Big theta notation

Let $t(n)$ and $g(n)$ can be any nonnegative functions defined on the set of natural numbers. The algorithm's running time $t(n)$ usually indicated by its basic operation count $C(n)$, and $g(n)$, some simple function to compare with the count.

Example 1:

$$n \in O(n^2), \quad 100n + 5 \in O(n^2), \quad \frac{1}{2}n(n-1) \in O(n^2),$$

$$n^3 \notin O(n^2), \quad 0.00001n^3 \notin O(n^2), \quad n^4 + n + 1 \notin O(n^2).$$

$$n^3 \in \Omega(n^2), \quad \frac{1}{2}n(n-1) \in \Omega(n^2), \quad \text{but } 100n + 5 \notin \Omega(n^2).$$

where $g(n) = n^2$.

(i) O - Big oh notation

A function $t(n)$ is said to be in $O(g(n))$, denoted $t(n) \in O(g(n))$, if $t(n)$ is bounded above by some constant multiple of $g(n)$ for all large n , i.e., if there exist some positive constant c and some nonnegative integer n_0 such that

$$t(n) \leq cg(n) \text{ for all } n \geq n_0.$$

Where $t(n)$ and $g(n)$ are nonnegative functions defined on the set of natural numbers.

O = Asymptotic upper bound = Useful for worst case analysis = Loose bound

FIGURE 1.5 Big-oh notation: $t(n) \in O(g(n))$.

FIGURE 1.5 Big-oh notation: $t(n) \in O(g(n))$.

Example 2: Prove the assertions $100n + 5 \in O(n^2)$.

Proof: $100n + 5 \leq 100n + n$ (for all $n \geq 5$)

$$= 101n$$

$$\leq 101n^2 \quad (\because n \leq n^2)$$

Since, the definition gives us a lot of freedom in choosing specific values for constants c and n_0 . We have $c=101$ and $n_0=5$

Example 3: Prove the assertions $100n + 5 \in O(n)$.

Proof: $100n + 5 \leq 100n + 5n$ (for all $n \geq 1$)

$$= 105n$$

$$\text{i.e., } 100n + 5 \leq 105n$$

$$\text{i.e., } t(n) \leq cg(n)$$

$\therefore 100n + 5 \in O(n)$ with $c=105$ and $n_0=1$

(ii) Ω - Big omega notation

A function $t(n)$ is said to be in $\Omega(g(n))$, denoted $t(n) \in \Omega(g(n))$, if $t(n)$ is bounded below by some positive constant multiple of $g(n)$ for all large n , i.e., if there exist some positive constant c and some nonnegative integer n_0 such that

$$t(n) \geq cg(n) \text{ for all } n \geq n_0.$$

Where $t(n)$ and $g(n)$ are nonnegative functions defined on the set of natural numbers.

Ω = Asymptotic lower bound = Useful for best case analysis = Loose bound

FIGURE 1.6 Big-omega notation: $t(n) \in \Omega(g(n))$.

Example 4: Prove the assertions $n^3 + 10n^2 + 4n + 2 \in \Omega(n^2)$.

Proof: $n^3 + 10n^2 + 4n + 2 \geq n^2$ (for all $n \geq 0$)

i.e., by definition $t(n) \geq cg(n)$, where $c=1$ and $n_0=0$

(iii) Θ - Big theta notation

A function $t(n)$ is said to be in $\Theta(g(n))$, denoted $t(n) \in \Theta(g(n))$, if $t(n)$ is bounded both above and below by some positive constant multiples of $g(n)$ for all large n , i.e., if there exist some positive constants c_1 and c_2 and some nonnegative integer n_0 such that

$$c_2 g(n) \leq t(n) \leq c_1 g(n) \text{ for all } n \geq n_0.$$

Where $t(n)$ and $g(n)$ are nonnegative functions defined on the set of natural numbers.

Θ = Asymptotic tight bound = Useful for average case analysis

FIGURE 1.7 Big-theta notation: $t(n) \in \Theta(g(n))$.

FIGURE 1.7 Big-theta notation: $t(n) \in \Theta(g(n))$.

Example 5: Prove the assertions $\frac{1}{2}n(n-1) \in \Theta(n^2)$.

Proof: First prove the right inequality (the upper bound):

$$\frac{1}{2}n(n-1) = \frac{1}{2}n^2 - \frac{1}{2}n \leq \frac{1}{2}n^2 \quad \text{for all } n \geq 0.$$

Second, we prove the left inequality (the lower bound):

$$\frac{1}{2}n(n-1) = \frac{1}{2}n^2 - \frac{1}{2}n \geq \frac{1}{2}n^2 - \left[\frac{1}{2}n\right]\left[\frac{1}{2}n\right] \quad \text{for all } n \geq 2.$$

$$\therefore \quad \frac{1}{2}n(n-1) \geq \frac{1}{4}n^2$$

$$\text{i.e.,} \quad \frac{1}{4}n^2 \leq \frac{1}{2}n(n-1) \leq \frac{1}{2}n^2$$

Hence, $\frac{1}{2}n(n-1) \in \Theta(n^2)$, where $c_2 = \frac{1}{4}$, $c_1 = \frac{1}{2}$ and $n_0 = 2$

Note: asymptotic notation can be thought of as "relational operators" for functions similar to the corresponding relational operators for values.

$$= \Rightarrow \Theta(),$$

$$\leq \Rightarrow O(),$$

$$\geq \Rightarrow \Omega(),$$

$$< \Rightarrow o(),$$

$$> \Rightarrow \omega()$$

- **MATHEMATICAL ANALYSIS FOR RECURSIVE ALGORITHMS**
- General Plan for Analyzing the Time Efficiency of Recursive Algorithms
 1. Decide on a parameter (or parameters) indicating an input's size.
 2. Identify the algorithm's basic operation.
 3. Check whether the number of times the basic operation is executed can vary on different inputs of the same size; if it can, the worst-case, average-case, and best-case efficiencies must be investigated separately.
 4. Set up a recurrence relation, with an appropriate initial condition, for the number of times the basic operation is executed.
 5. Solve the recurrence or, at least, ascertain the order of growth of its solution.

EXAMPLE 1: Compute the factorial function $F(n) = n!$ for an arbitrary nonnegative integer n . Since $n! = 1 \cdot \dots \cdot (n-1) \cdot n = (n-1)! \cdot n$, for $n \geq 1$ and $0! = 1$ by definition, we can compute $F(n) = F(n-1) \cdot n$ with the following recursive algorithm. (ND 2015)

ALGORITHM $F(n)$

//Computes $n!$ recursively

//Input: A nonnegative integer n

//Output: The value of $n!$

if $n = 0$ **return** 1

else return $F(n-1) * n$

Algorithm analysis

- For simplicity, we consider n itself as an indicator of this algorithm's input size. i.e. 1.
- The basic operation of the algorithm is multiplication, whose number of executions we denote $M(n)$. Since the function $F(n)$ is computed according to the formula $F(n) = F(n-1) \cdot n$ for $n > 0$.
- The number of multiplications $M(n)$ needed to compute it must satisfy the equality

$$M(n) = M(n-1) + 1 \quad \text{for } n > 0$$

\uparrow
 To compute
 $F(n-1)$

\uparrow
 To multiply
 $F(n-1)$ by n

$M(n-1)$ multiplications are spent to compute $F(n-1)$, and one more multiplication is needed to multiply the result by n .

Recurrence relations

The last equation defines the sequence $M(n)$ that we need to find. This equation defines $M(n)$ not explicitly, i.e., as a function of n , but implicitly as a function of its value at another point, namely $n - 1$. Such equations are called *recurrence relations* or *recurrences*.

Solve the recurrence relation $M(n) = M(n - 1) + 1$, i.e., to find an explicit formula for $M(n)$ in terms of n only.

To determine a solution uniquely, we need an initial condition that tells us the value with which the sequence starts. We can obtain this value by inspecting the condition that makes the algorithm stop its recursive calls:

if $n = 0$ return 1.

This tells us two things. First, since the calls stop when $n = 0$, the smallest value of n for which this algorithm is executed and hence $M(n)$ defined is 0. Second, by inspecting the pseudocode's exiting line, we can see that when $n = 0$, the algorithm performs no multiplications.

Thus, the recurrence relation and initial condition for the algorithm's number of multiplications $M(n)$:

$$M(n) = M(n - 1) + 1 \text{ for } n > 0,$$

$$M(0) = 0 \quad \text{for } n = 0.$$

Method of backward substitutions

$$M(n) = M(n - 1) + 1$$

$$\text{substitute } M(n - 1) = M(n - 2) + 1$$

$$= [M(n - 2) + 1] + 1$$

$$= M(n - 2) + 2$$

$$\text{substitute } M(n - 2) = M(n - 3) + 1$$

$$= [M(n - 3) + 1] + 2$$

$$= M(n - 3) + 3$$

...

$$= M(n - i) + i$$

...

$$= M(n - n) + n$$

$$= n.$$

Therefore $M(n) = n$

EXAMPLE 2: consider educational workhorse of recursive algorithms: the *Tower of Hanoi* puzzle. We have n disks of different sizes that can slide onto any of three pegs. Consider A (source), B (auxiliary), and C (Destination). Initially, all the disks are on the first peg in order of size, the largest on the bottom and the smallest on top. The goal is to move all the disks to the third peg, using the second one as an auxiliary.

FIGURE 1.8 Recursive solution to the Tower of Hanoi puzzle.

ALGORITHM TOH(n , A, C, B)

//Move disks from source to destination recursively

//Input: n disks and 3 pegs A, B, and C

//Output: Disks moved to destination as in the source order.

if $n=1$

 Move disk from A to C

else

 Move top $n-1$ disks from A to B using C

 TOH($n - 1$, A, B, C)

 Move top $n-1$ disks from B to C using A

 TOH($n - 1$, B, C, A)

Algorithm analysis

The number of moves $M(n)$ depends on n only, and we get the following recurrence equation for it: $M(n) = M(n - 1) + 1 + M(n - 1)$ for $n > 1$.

With the obvious initial condition $M(1) = 1$, we have the following recurrence relation for the number of moves $M(n)$:

$$M(n) = 2M(n - 1) + 1 \text{ for } n > 1,$$

$$M(1) = 1.$$

$$M(1) = 1.$$

We solve this recurrence by the same method of backward substitutions:

$$\begin{aligned}
 M(n) &= 2M(n-1) + 1 & \text{sub. } M(n-1) &= 2M(n-2) + 1 \\
 &= 2[2M(n-2) + 1] + 1 \\
 &= 2^2M(n-2) + 2 + 1 & \text{sub. } M(n-2) &= 2M(n-3) + 1 \\
 &= 2^2[2M(n-3) + 1] + 2 + 1 \\
 &= 2^3M(n-3) + 2^2 + 2 + 1 & \text{sub. } M(n-3) &= 2M(n-4) + 1 \\
 &= 2^4M(n-4) + 2^3 + 2^2 + 2 + 1 \\
 &\dots \\
 &= 2^iM(n-i) + 2^{i-1} + 2^{i-2} + \dots + 2 + 1 = 2^iM(n-i) + 2^i - 1.
 \end{aligned}$$

$$\begin{aligned}
 &\dots \\
 &\text{Since the initial condition is specified for } n = 1, \text{ which is achieved for } i = n - 1, \\
 &M(n) = 2^{n-1}M(n - (n - 1)) + 2^{n-1} - 1 = 2^{n-1}M(1) + 2^{n-1} - 1 = 2^{n-1} + 2^{n-1} - 1 = 2^n - 1.
 \end{aligned}$$

Thus, we have an exponential time algorithm

- **MATHEMATICAL ANALYSIS FOR NON-RECURSIVE ALGORITHMS**
- General Plan for Analyzing the Time Efficiency of Nonrecursive Algorithms
 - 1. Decide on a parameter (or parameters) indicating an input's size.
 - 2. Identify the algorithm's basic operation (in the innermost loop).
 - 3. Check whether the number of times the basic operation is executed depends only on the size of an input. If it also depends on some additional property, the worst-case, average-case, and, if necessary, best-case efficiencies have to be investigated separately.
 - 4. Set up a sum expressing the number of times the algorithm's basic operation is executed.
 - 5. Using standard formulas and rules of sum manipulation either find a closed form formula for the count or at the least, establish its order of growth.

EXAMPLE 1: Consider the problem of finding the value of the largest element in a list of n numbers. Assume that the list is implemented as an array for simplicity.

ALGORITHM MaxElement($A[0..n-1]$)

//Determines the value of the largest element in a given array

//Input: An array $A[0..n-1]$ of real numbers

//Output: The value of the largest element in A

maxval $\leftarrow A[0]$

for $i \leftarrow 1$ to $n-1$ do

 if $A[i] > \text{maxval}$

 maxval $\leftarrow A[i]$

return maxval

Algorithm analysis

- The measure of an input's size here is the number of elements in the array, i.e., n .
- There are two operations in the for loop's body:
 - The comparison $A[i] > \text{maxval}$ and
 - The assignment $\text{maxval} \leftarrow A[i]$.
- The comparison operation is considered as the algorithm's basic operation, because the comparison is executed on each repetition of the loop and not the assignment.
- The number of comparisons will be the same for all arrays of size n ; therefore, there is no need to distinguish among the worst, average, and best cases here.
- Let $C(n)$ denotes the number of times this comparison is executed. The algorithm makes one comparison on each execution of the loop, which is repeated for each value of the loop's variable i within the bounds 1 and $n - 1$, inclusive. Therefore, the sum for $C(n)$ is calculated as follows:

$$c(n) = \sum_{i=1}^{n-1} 1$$

i.e., Sum up 1 in repeated $n-1$ times

$$c(n) = \sum_{i=1}^{n-1} 1 = n - 1 \in \Theta(n)$$

ALGORITHM MatrixMultiplication($A[0..n-1, 0..n-1]$, $B[0..n-1, 0..n-1]$)
//Multiplies two square matrices of order n by the definition-based algorithm
//Input: Two $n \times n$ matrices A and B
//Output: Matrix $C = AB$
for $i \leftarrow 0$ to $n-1$ do
 for $j \leftarrow 0$ to $n-1$ do
 $C[i, j] \leftarrow 0.0$
 for $k \leftarrow 0$ to $n-1$ do
 $C[i, j] \leftarrow C[i, j] + A[i, k] * B[k, j]$
return C

Algorithm analysis

- An input's size is matrix order n .
- There are two arithmetical operations (multiplication and addition) in the innermost loop. But we consider multiplication as the basic operation.
- Let us set up a sum for the total number of multiplications $M(n)$ executed by the algorithm. Since this count depends only on the size of the input matrices, we do not have to investigate the worst-case, average-case, and best-case efficiencies separately.
- There is just one multiplication executed on each repetition of the algorithm's innermost loop, which is governed by the variable k ranging from the lower bound 0 to the upper bound $n - 1$.
- Therefore, the number of multiplications made for every pair of specific values of variables i and j is

$$\sum_{k=0}^{n-1} 1$$

The total number of multiplications $M(n)$ is expressed by the following triple sum:

$$M(n) = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \sum_{k=0}^{n-1} 1$$

Now, we can compute this sum by using formula (S1) and rule (R1)

$$M(n) = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \sum_{k=0}^{n-1} 1 = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} n = \sum_{i=0}^{n-1} n^2 = n^3.$$

The running time of the algorithm on a particular machine m , we can do it by the product

$$T(n) \approx c_m M(n) = c_m n^3,$$

If we consider, time spent on the additions too, then the total time on the machine is

$$T(n) \approx c_m M(n) + c_a A(n) = c_m n^3 + c_a n^3 = (c_m + c_a) n^3$$
